

Communicating risks and benefits to cardiology patients

Trying to explain potential outcomes, and their likelihoods, is a challenge. Indeed, patients who just had a stent procedure remember few of the related risks and benefits [1]. Patients are often unfamiliar with the terminology, vary widely in health status, numeracy, health literacy, and information preferences. Complicating things further is aiming to ensure that patients understand the “material risks” for them as individuals: a matter not just of probability, but also the impact it could have on them personally.

This task is not only an ethical imperative but a legal one, enshrined in law in many countries, such as the 2015 Montgomery judgment in the UK (Fig 1). At the Winton Centre, our research into how individuals understand risk aims to offer a few considerations and recommendations to help clinicians achieve this.

“...the doctor’s advisory role involves dialogue, the aim of which is to ensure that the patient understands the seriousness of her condition, and the anticipated benefits and risks of the proposed treatment and any reasonable alternatives, so that she is then in a position to make an informed decision. This role will only be performed effectively if the information provided is comprehensible. The doctor’s duty is not therefore fulfilled by bombarding the patient with technical information which she cannot reasonably be expected to grasp, let alone by routinely demanding her signature on a consent form.”

Communicating numbers

In a recent series of surveys covering more than 12,000 people and 12 countries we asked the question “Which of the following numbers represents the biggest risk of getting a disease: 1 in 100, 1 in 1000, or 1 in 10?”. One in six participants answered incorrectly. Other research shows

over a quarter could not answer the question “If a person’s chance of getting a disease is 20 out of 100, this would be the same as having a ___% chance of getting the disease”[2].

To try to avoid these misunderstandings, some clinicians use words instead of numbers[3], but this can backfire. For example, patients who were told that pancreatitis was a “rare” complication of simvastatin or atorvastatin assumed that its incidence was 450 times higher than it actually was, and had more negative impressions of the medication than patients who were told the risks numerically[4].

When making comparisons, keep the denominator the same (eg. “1 out of 200 people” vs “4 out of 200 people”, not “1 in 200” vs “1 in 50”), and compare risks to benefits in the same terms wherever possible; be explicit about time frames (eg. “a year from now”); be clear about the reference class (eg. “people like you who have this procedure”); frame outcomes in a balanced way (eg. “1 would experience... while the other 199 would experience...”). If available statistics are not necessarily appropriate for this patient, this should be made explicit (eg. “We usually say the risk is... But for you, it may be higher/lower, because...”).

Using graphics can allow people to ‘see’ the numbers and appreciate their context. For example showing outcomes for 100 people, using different shapes or colours to represent patients who had different experiences, can give an instant impression. Those with higher numeracy tend to count the icons, those with lower numeracy use the impression of the area [5]. See Figure 2 for an example.

Figure 2: Icon arrays illustrating the outcomes of patients described in a trial of adrenaline for those suffering an out-of-hospital cardiac arrest[6]. The graphics give an instant impression of the numbers, and reduces the risk of positive or negative-only framing by showing both positive and negative outcomes simultaneously.

Communicating uncertainty

Although everyone wants certainty, we must be honest about the unknown. A statistic cannot represent a patient's personal risk. Discuss factors that may affect their risk as compared to conventional statistics and acknowledge the inevitable uncertainties. Rounding uncertain numbers ("5" rather than "4.8") can make them easier to interpret and correctly imply that they are not exactly known. When confidence intervals are wide, stating them as a range ("anywhere from 2 people to 5 people...") may underscore the lack of certainty. However, presenting extra numbers may confuse a patient further if they have to be rattled off in a short time: graphical representations of uncertainty may help avoid overload.

Describing potential negative outcomes

The language chosen to describe outcomes is as important as the language chosen to describe probability. It should convey some sense of severity, and what it actually means for the patient (e.g., effects on quality of life etc.). For example, the word “bleeding” does not distinguish between a paper cut and severe blood loss. Being explicit about the duration of effects can also be important. In interviews with women who had undergone breast cancer treatment, we found that several who had experienced chronic consequences of treatment did not feel adequately informed of this possibility. Although they had been warned that side effects could be very severe, they had not realized that long-term effects were possible.

However, one can go overboard. It is well-known that visualizing negative scenarios can lead to substantial overestimation of their probabilities. This may be particularly important in acute care scenarios where emotions and fear are already likely to be running high.

In conclusion, then, avoid using words to convey likelihoods: use numbers and support them with graphics wherever possible. Be upfront and as precise as possible about uncertainties (again, using numerical ranges rather than verbal cues of uncertainty where possible). Be as balanced as you can about both benefits and risks, and avoid framing the numbers in just one direction. And the best way to check whether you have been successful in your communication is to stop and ask the patient to explain back what they have understood: this gives you a chance to assess what they’re understanding as well as what’s important to them.
